ABSTRACT Artificial solids composed of semiconductor quantum dots (QDs) are being developed for large-area electronic and optoelectronic applications, but these materials often have defect-induced in-gap states (IGS) of unknown chemical origin. Here we performed scanning probe based spectroscopic analysis and density functional theory calculations to determine the nature of such states and their electronic structure. We found that IGS near the valence band occur frequently in the QDs except when treated with reducing agents. Calculations on various possible defects and chemical spectroscopy revealed that molecular oxygen is most likely at the origin of these IGS. We expect this impurity-induced deep IGS to be a common occurrence in ionic semiconductors, where the intrinsic vacancy defects either do not produce IGS or produce shallow states near band edges. Ionic QDs with surface passivation to block impurity adsorption are thus ideal for high-efficiency optoelectronic device applications.

The evolution of semiconductor electronics and optoelectronics began with the controlled doping of impurity atoms into semiconductor crystals, which opened the way to engineer their charge transport properties.1 On the other hand, unwanted impurities or defects can hinder transport and limit device performance.2 The development of nanomaterials of controlled size made it possible to engineer the band gap and tune the electronic properties from the bottom up. As a trade-off, the impact of surface impurities on the electronic properties of nanomaterials is more prominent due to the large surface-to-volume ratio and strong quantum confinement effects.3–5 For collooidally synthesized nanocrystals or quantum dots in particular, surface-related in-gap states (IGS) are believed to assist the recombination of photoexcited charge carriers,6 which limits the optoelectronic device efficiency.7,8 Here we focus on PbS quantum dots (QDs), which have produced the best-performing solar cells.9–11 Recently, Bawendi et al. reported the presence of emissive IGS that form an "effective band" inside the band gap and ~0.2 eV away from the band edge, which were believed to be at the origin of the high open-circuit voltage deficit in the QD solar cells.12 Remarkably, this is in good agreement with our previous work, where we found a band of IGS ≈ 0.2 eV above the valence band of PbS QDs, which form percolation pathways assisting carrier transport.13,14 In addition, Sargent et al. and Klimov et al. found similar IGS using transient absorption and scanning tunneling spectroscopy (STS) methods.7,8,15

Although the existence and the energy level of IGS have been established, until now the nature of the IGS is still unclear. Theoretical predictions include nonstoichiometry of the constituent atoms,16 incomplete ligand passivation,8 and charge-induced surface reconstruction.17 The bottleneck for the understanding of IGS is the complicated surface chemistry and ligand passivation structure of the QDs, which makes it difficult to correlate theory with experimental investigations. We overcame this obstacle with a combined effort of state-of-the-art density functional theory (DFT) calculations and chemical spectroscopy on real PbS QD systems consisting of over a thousand atoms and successfully...
identified the surface ligand passivation structure of the QDs.\textsuperscript{18}

Here we extend this approach to investigate the chemical origin of IGS in PbS QDs. One experimental challenge is the accurate measurement of the energy levels of these defect states. Traditional methods include transient photovoltage measurements, thermal admittance spectroscopy, and deep level transient spectroscopy.\textsuperscript{5,15,20} These techniques provide quantitative information on the concentration of IGS, but cannot determine their energy levels. Photoluminescence, transient absorption, and photocurrent spectroscopy can probe the optical transitions in QD solids,\textsuperscript{4,7,8,12,20,21} but the correlation of the various transitions with IGS is not straightforward, considering the presence of multiple intraband transitions and vibrational absorption of the organic ligands.\textsuperscript{22} X-ray spectroscopy techniques can probe the energy level of electronic states, but the resolution is not high enough to resolve individual IGS peaks.\textsuperscript{23–25} In fact, these spectroscopy results obtained by different groups on similar PbS QD systems vary by several 100 meV.\textsuperscript{24,25}

We overcome this obstacle by using Kelvin probe force microscopy (KPFM) based surface potential spectroscopy (SPS)\textsuperscript{26} to directly resolve the energetic position of the IGS. Correlation with DFT calculations and X-ray photoelectron spectroscopy (XPS) allow us to identify the source of IGS. Previously KPFM has been used to image the local work function and built-in potential in various colloidal nanomaterials.\textsuperscript{27} However, a KPFM-based spectroscopic study on the density of states of QDs has not been reported before. Our methodology for studying defects in QDs, with more structural variability than the bulk single crystals explored by traditional surface science, is generally applicable to solution-processed materials, such as organic thin films and perovskite materials.

**RESULTS AND DISCUSSION**

**Experimental Observation of in-Gap States.** The PbS QDs studied here have an average diameter of 5.5 nm with a $\sim$0.9 eV band gap. As-synthesized colloidal QDs are typically capped with long insulating ligands.\textsuperscript{18} For lead chalcogenide (PbX, X = S, Se) QDs, various ligand exchange processes have been explored to reduce interparticle distance and enable electron conduction in a QD solid. Here we explore treatments with 1,2-ethanedithiol (EDT), 3-mercaptopropionic acid (MPA), and hydrazine (HYD) that have been reported to produce ambipolar QD field effect transistors (FETs). The resulting QDs are labeled PbS-EDT, PbS-MPA, and PbS-HYD, respectively.

To study the IGS, in our previous work we performed scanning tunneling spectroscopy on individual PbS-EDT QDs deposited on indium tin oxide (ITO) substrate to obtain their electronic density of states (DOS).\textsuperscript{13} A heterogeneous distribution of DOS was observed on measurements over tens of QDs, with about half of them showing IGS. These states are located 0.05–0.1 eV above the Fermi level and 0.15–0.3 eV above the 1Sh states (valence band). The actual percentage of QDs with IGS can be higher since STS is only sensitive to states localized on the top surface of the QD or with wave functions that extend all the way to the surface. The energy position of the 1Sh states was found to fluctuate from particle to particle, but compared to the 1Sh states (conduction band) they are always closer to the Fermi level. This is in agreement with the previously observed p-type doping of EDT-treated lead chalcogenide QDs.\textsuperscript{28,29}

Here we focus on another way to measure the energy level of IGS, KPFM,\textsuperscript{26,30} which probes the change of surface potential as a function of gate bias in a QD monolayer FET. Since the occupation of states is electrostatically tuned by the gate bias in the FET, we can use KPFM to extract the density of states. In a simple electrostatic model based on the planar capacitor geometry made by the gate and the QD monolayer, the charge density in the QDs can be obtained from the measured surface potential relative to the gate voltage (Supporting Information (SI) 2.3). This spectroscopy method (SPS) has previously been used to analyze the IGS in organic thin films.\textsuperscript{26,31} Since the lateral resolution of our KPFM setup is $\sim$20–50 nm using a normal metal-coated tip (not the QD-coated tip previously used for $\sim$10 nm resolution imaging),\textsuperscript{18} the measured DOS is an average over tens of QDs and thus represents the ensemble properties of the QD solid, in contrast with STS, which measures individual QDs. Therefore, in QD systems that are typically heterogeneous in their surface chemistry and in their electronic structure, this technique provides a useful method to characterize the overall change of electronic structure with different surface chemical treatments. We can see that the DOS obtained by SPS accurately resolves the band edge of the 1Sh states and IGS of PbS-EDT (Figure 1A). The IGS is $\sim$0.2 eV higher than the 1Sh states, in agreement with our previous STS results.\textsuperscript{13} We are unable to probe the DOS beyond the 1Sh/IGS band edge due to the limited charge injection capability of the FET setup (SI 2.3). This points to the main difference between the SPS technique and the STS technique: the former is based on electrostatic interactions and only probes the states that can be stably occupied and emptied, while the later is based on the quantum tunneling of electrons and probes a large range of states that electrons can tunnel into/out of.\textsuperscript{13,15,33,34}

It has been reported that MPA passivates the QD surface more completely than EDT.\textsuperscript{7,8,21} Our SPS results on PbS-MPA (Figure 1B), however, reveal the presence of IGS at nearly the same level as those in the PbS-EDT, indicating that the IGS are not due to incomplete ligand passivation. We further performed SPS on
PbS-HYD (Figure 1C), where the hydrazine acts as a reducing agent that was previously assumed to be able to repair surface defects of lead chalcogenide QDs.35,36 Note that the HYD treatment was performed directly on the original oleate-coated QDs,35 instead of on the ligand-exchanged QDs as reported before.37 We found that PbS-HYD has a clean band gap with no observable IGS. This result suggests that the previously observed IGS may be related with adsorbed species from the environment that are removed by the hydrazine treatment. To test this assumption, we exposed the PbS-HYD QDs to air for 30 s and found that IGS reappeared at \( \sim 0.1 \) eV above the 1Sh states (Figure 1D). This suggests that either oxygen or water is at the origin of the observed IGS. As we show next by theoretical analysis and chemical spectroscopy, O\(_2\) is the responsible species. Note that the energy levels of the 1Sh states of all the samples are measured to be at \(-5.1\) to \(-5.0\) eV (with respect to the vacuum level), in agreement with previous results for 5.5 nm PbS QDs,38 further confirming the assignment of all the band edge states.

**Theoretical Calculations on in-Gap States.** In our DFT calculations we used PbS QDs of 4 nm diameter, for which we obtained a band gap of 0.94 eV. This value is slightly smaller than the experimentally observed 1.1 eV band gap for 4 nm PbS QDs,38 due to the well-known band gap underestimate in DFT theory.39 Nevertheless, since the calculated band gap matches that of the 5.5 nm PbS QD used in our experiments, we expect the calculated DOS to also match our experimental observations. We subsequently calculated the formation energy and electronic structure of QDs with various possible vacancies and impurities. Since the QDs are synthesized in solution, we need to consider both neutral vacancies and charged ionic vacancies (with organic counterions in the nearby solution environment). We found that neutral atomic vacancies (Pb, S, L, where L refers to ligand), neutral divacancies (PbS, PbL\(_2\)), and charged ion vacancies (Pb\(^{2+}\), S\(^{2-}\), L\(^{-}\)) have formation energies in the range 1.6–2.3, 0.8–1.8, and \(-0.8–1\) eV, respectively. Thus, the formation of neutral atomic vacancies during QD growth in solution is very unlikely, while charged ion vacancies are most likely to form. Our calculations show that PbS and S\(^{2-}\) vacancies produce IGS near the conduction band, while all other charged ion vacancies and neutral divacancies do not induce IGS (Figure S6). This leads us to conclude that external molecules adsorbed on the QD surface are at the origin of the observed IGS. These molecules need to be small and reactive in order to adsorb on the QD surface after diffusing through the ligands. Prime candidates are water and oxygen because they are present (in trace amounts) during synthesis and during glovebox storage.

The calculations show that adsorbed water does not produce IGS (Figure S7), while adsorbed molecular oxygen produces IGS slightly above the valence band. Using the spin-polarized generalized gradient approximation (GGA), we found two unoccupied states at
Figure 2. DFT calculation reveals that molecular oxygen is at the origin of IGS. (A) DFT-calculated probability density distribution from the wave function of the two unoccupied IGS derived from $O_2$ adsorbed on a 4 nm PbS QD surface. These states are formed by hybridization of the oxygen $\pi^*$ and $\pi$ orbitals with the 1$S_n$ state of the QD. (B) DFT-calculated spin-polarized partial density of states (PDOS) for PbS QD with one adsorbed $O_2$ molecule in the GGA approximation. The contributions from different elements are shown in color (Pb: gray, S: yellow, Cl: green, O: red). $E_f$ refers to the Fermi level. There are two empty IGS at 0.07 eV ($\pi^*$) and 0.18 eV ($\pi$) above the 1$S_n$ state due to triplet states of $O_2$. Inset: Expanded view of the IGS and 1$S_n$ states.

0.07 and 0.18 eV above the 1$S_n$ state (Figure 2). A higher level hybrid functional imposes a 0.13 eV correction on these states, shifting them up to 0.20 and 0.31 eV above 1$S_n$ (SI 3.8). The energies of these states match those of the experimentally observed IGS in PbS-EDT, PbS-MPA, and the 30 s air exposed PbS-HYD. The two empty $O_2$-derived IGS are formed by coupling of the two unoccupied $\pi^*$ orbitals of molecular oxygen with the 1$S_n$ state of the QD. The wave function density of the two IGS extends deep into the QD (Figure 2A). At the center, the wave function density still has a finite value that is 1.07% of the maximum density inside the QD. Accordingly to the Bader charge analysis of the total charge density, a partial electron transfer of 0.33 e$^-$ occurs from the QD to the oxygen molecule. The O–O distance in the adsorbed $O_2$ is 1.278 Å, a slight increase compared to the free molecule value (1.241 Å). The calculated formation energy of the oxygen on the QD surface is $-0.32$ eV (Table 1), in contrast with the positive formation energies of various vacancy defects. Since the van der Waals interaction was not taken into account in the calculation, the actual formation energy can be lower (larger in absolute value) than $-0.32$ eV. The surface ligand species and their distribution may also affect the absolute values of the formation energy. However, we expect the relative formation energy difference between different adsorption species to be reasonable.

We calculated also the DOS when oxygen molecules are dissociated on the QD surface (in minimum energy configuration) and found that no IGS are created in that case (Figure S8). Furthermore, substitutional atomic oxygen defects (where an oxygen atom replaces a sulfur atom on the QD surface) were found to not produce IGS either. Therefore, among the theoretically calculated intrinsic and external defects, only molecular oxygen produces IGS with energy levels matching the experimental results.

### Spectroscopic Evidence and Further Theoretical Support on the Origin of IGS

To confirm the existence and analyze the concentration of molecular oxygen, we performed X-ray photoelectron spectroscopy, targeting the O 1s emission peak (Figure 3). All the samples shown in Figure 1 were measured except PbS-MPA, where the ligand contains oxygen (thus complicating the spectra). XPS confirms the existence of $O_2$ (533.9 eV) on PbS-EDT. Another peak at 532.1 eV corresponds to the COO$^-$ groups, likely arising from the residual unexchanged oleate ligands. In PbS-HYD QDs, in contrast, $O_2$ species are absent. When exposed to 1 atm of a 25% $O_2$/75% Ar gas mixture for 30 s, the 533.9 eV $O_2$ peak appeared on the PbS-HYD. The 531.3 eV peak corresponds to –OH groups that were present on the oleate-passivated QDs and not fully removed by the HYD treatment. Peak area analysis shows that the concentration of $O_2$ on PbS-EDT and on the 30 s exposed PbS-HYD is roughly similar, approximately 10 molecules per QD on average (SI 4.2). The amount of $O_2$ on PbS-HYD remained constant after a 10 min exposure (although the amount of atomic oxygen species increased) (Figure S10). The correlation of the presence or absence of $O_2$ with the formation of IGS, together with the theoretical results on the effect of $O_2$ in producing the IGS, lends strong support to our conclusion on the origin of the IGS. It should be noted that the XPS spectral resolution is limited by the small amount of oxygen species present on the QDs, and the resolution on the PbS-EDT sample is slightly worse than on the PbS-HYD.

$^*$ Substitutional atomic defect where an oxygen atom replaces a sulfur atom on the QD surface.
Similar to the single O2 case, using the higher level STM tip may not be sensed by STS, as explained before. In the two O2 case, resulting in four states hybrid functional we expect the same 0.13 eV upshift down states (0.06 and 0.18 eV above the 1Sh state). We expect that the energy level of the IGS in the case of multiple O2 on one QD will not change significantly as long as these states are not strongly coupled.

With two O2 on the QD, charge transfer from QD to each of the O2 molecules estimated from Bader charge analysis decreases to 0.30 e\textsuperscript{-} per molecule. This is because the QD is resistant to more electron withdrawal. As a result, the formation energy increases to −0.22 eV per molecule. With more O2 on the QD, we expect a further increase of formation energy. This might be the reason that the amount of O2 saturates after the PbS-HYD was exposed to oxygen for only 30 s (as shown by XPS). The formation energies of various possible impurity defects are shown in Table 1. Molecular oxygen has the largest formation energy (smallest in absolute value) among the considered impurities and is the only one that produces IGS. We need to note that prolonged oxidation of PbS QDs results in the formation of various oxide species such as PbSO\textsubscript{3} and PbSO\textsubscript{4}.\textsuperscript{41} In that case the simple vacancy and impurity defect picture is not sufficient to describe the electronic structure of the QD, since the composition is significantly modified.

**Further Discussions.** We have considered various possible defects that can form during the solution phase synthesis process, which is the first step of all the device fabrication based on colloidal QDs. Among these defects, molecular oxygen, an unintentional impurity that is hard to avoid, is found to be the most likely source of IGS near the valence band. Various postsynthetic treatments, on the other hand, can modify the amount and/or type of defects, thus changing the IGS. The hydrazine treatment shown here is one example of removing O2 and eliminating IGS. Another postsynthesis approach of electronic modification is stoichiometry control via deposition of excess lead or chalcogen.\textsuperscript{42,43} Although neutral atomic vacancies are unlikely to form during solution synthesis (as discussed before), this postsynthesis control can produce QDs with excess Pb or S (i.e., QD with neutral S or Pb vacancies). According to previous calculations\textsuperscript{8,16} and our own DFT results (not shown here), neutral Pb vacancies produce IGS near the valence band, while neutral S or L (ligand) vacancies produce IGS near the conduction band.

The intrinsic defect physics of lead chalcogenide QDs can be understood in the general scheme of ionic semiconductors. Similar to methylammonium lead iodide perovskite systems,\textsuperscript{44} charge-balanced (surface fully passivated by ligands) PbS QDs do not show IGS. This has been demonstrated by DFT calculations on PbS QDs passivated with oleic acid and hydroxyl groups,\textsuperscript{18} with EDT,\textsuperscript{16} and with MPA + Cl.\textsuperscript{8} All the above ligands form ionic bonds with the surface Pb\textsuperscript{2+}, thus maintaining the overall stoichiometry of the Pb-rich QD.\textsuperscript{45–47} In our work, to make DFT calculations

![Figure 3](Image 75x438 to 255x735)
possible on a QD as large as 4 nm, we used Cl as the passivation ligand and found a clean band gap after complete passivation. As long as the ligands form ionic bonds with Pb, different ligand species are expected to have similar effects on IGS properties. This is in agreement with our experimental results, where similar IGS were found on QDs with three different chemical treatments (EDT, MPA, and HYD+O2).

As explained before, as-synthesized QDs in solution tend to not have neutral defects due to their large formation energy. To fabricate electronically active devices, however, the QD solids typically need to go through a ligand exchange process, which can result in a loss of ligands, leading to QDs with excess cation atoms (Pb in our case). These neutral vacancy defects, if present, will induce IGS near the conduction band. However, the fact that we do not observe n-type IGS indicates that either our QDs are well passivated by ligands (i.e., there is no ligand vacancy) or the IGS induced by ligand vacancies are too close (within ~50 meV) to the conduction band to be observed. In either case, O2 remains the only experimentally observable deep IGS in typical ligand-exchanged QD solids that can be detrimental to optoelectronic devices.

It has previously been found that oxygen exposure can induce p-type doping in lead chalcogenide QDs, supporting the O2-induced IGS mechanism. Moreover, these QD solids with various ligand treatments (EDT, n-butylamine, MPA, etc.) exhibit unintentional p-type doping even in inert atmosphere, with carrier densities of $10^{16}$–$10^{17}$ cm$^{-3}$ for QDs of 5–6 nm diameter. This doping effect is also mainly due to the IGS produced by O2, whose surface concentration on the QD is limited by the energy cost of the charge transfer from the QD to the adsorbed O2 (as explained above). From our STS results on the PbS-EDT we obtain an average Fermi level ($E_F$)–1S$_h$ state ($E_v$) separation of 0.15 eV (averaged over the QDs with observable IGS, since those without IGS tend to have 1S$_h$ states far from the Fermi level and are thus electronically inactive). The estimated effective density of valence band states for our 5.5 nm PbS QD solids is $n_v = 2.1 \times 10^{19}$ cm$^{-3}$ (see Methods). Thus, at room temperature the hole carrier density can be calculated as

$$p = n_v \exp\left(-\frac{E_F - E_v}{kT}\right) = 6.4 \times 10^{16} \text{ cm}^{-3}$$

in good agreement with previous results. This quantitative agreement reveals that our proposed IGS mechanism is generally applicable to lead chalcogenide QDs, where unintentional doping can be induced by surface-saturated O2.

**CONCLUSION**

We have identified molecular oxygen as the dominant source of IGS in colloidal PbS quantum dots. The in-gap electronic structure of the QDs is immune to most of the charged ion vacancies that may form during the synthesis process. To engineer IGS-free QDs for optoelectronic applications, we need to first reduce the surface oxygen during the postsynthesis treatment process and ideally also fully passivate the surface with ligands that can block the readsoption of O2 on QDs.

**METHODS**

Synthesis of PbS quantum dots was done following a previously reported procedure. QD size and morphology were measured by transmission electron microscopy, while their band gap is determined by UV–vis absorption spectroscopy. QD monolayers were prepared by spin-coating colloidal QDs on a substrate followed by chemical treatments and solvent washing to obtain a monolayer with different ligands or different

**Figure 4.** DFT calculations of two O2 molecules on a PbS quantum dot. (A) Integrated probability density distribution of the states between $E_F$ and $E_F + 0.25$ eV. (B) Calculated spin-polarized DOS in the GGA approximation. The inset is an expanded view of the IGS. Four IGS are present at 0.05 eV ($\pi^*$) and 0.16 eV ($\pi$) above the 1S$_h$ state (spin-up) and at 0.06 eV ($\sigma^*$) and 0.18 eV ($\sigma$) above the 1S$_h$ state (spin-down).
surface chemistry. The species of the surface ligands were characterized by Fourier transform infrared spectroscopy measurements. All of the sample preparation procedures were done in an Ar glovebox with <1 ppm oxygen. Sample transfer to the measurement chambers of KPFM, STM, and XPS was done using a nitrogen glovebag or portable vacuum chamber. During the whole sample preparation, transfer, and measurement process the sample was never exposed to air.

STM measurements were performed with a home-built system operated at 77 K in ultrahigh vacuum. The differential conductance (dI/dV) spectra were measured using a lock-in technique with fixed tip to sample distance. The electronic structure of the tip was checked by recording background spectra on the bare ITO substrate, before and after measuring the STS spectra of each QD.

KPFM was done using a home-built setup that operates in single-pass, frequency feedback, noncontact mode. The AFM tip used to simultaneously probe the topography and surface potential is silicon coated with Ti/Pt, with a typical tip radius of ~28 nm.

DFT calculations were carried out using the Vienna Ab Initio Simulation Package (VASP), using the generalized gradient approximation (GGA) functional (PW91) and a hybrid functional (HSE06).

XPS was done on thin-film samples deposited on Au. The O 1s peak energy was calibrated by the Pb 4f peak. Gaussian–Lorentzian peak fitting was performed by fixing the peak energy and width of each component to be the same, for all four samples (PbS-EDT, PbS-HYD, 30 s exposed PbS-HYD, 10 min exposed PbS-HYD). Concentration of the O 1s species was estimated by comparing the O 1s and the Pb 4f peak areas and considering the atomic sensitivity factor and geometric factors.

The effective density of hole states is estimated using

\[ n_h = \frac{8\nu_{eff}}{V} \]

considering that the valence band of PbS QDs is 8-fold degenerate.\(^{30}\) \(\nu_{eff}\) is the effective average volume occupied by each QD. Assuming that the QDs have a spherical shape, with a volume fill fraction of 0.5 and an inter-QD distance of 1.6 nm for PbS-EDT,\(^{51}\) we have \(V_{eff} = 3.75 \times 10^{-13} \text{ cm}^3\). Thus, \(n_h = 2.1 \times 10^{10} \text{ cm}^{-3}\).
